Geometry of Data

Question: Can you guess the equation that defines the decision boundary below?

Geometry of Data

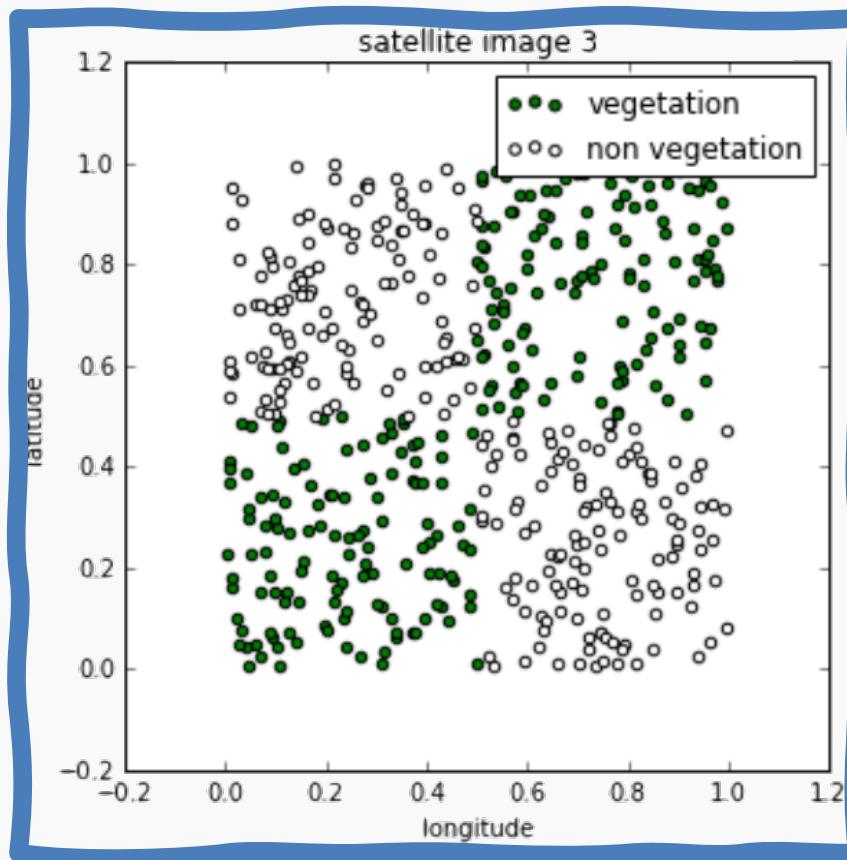

Question: Can you guess the equation that defines the decision boundary below?

$$-0.8x_1 + x_2 = 0 \Rightarrow x_2 = 0.8x_1 \Rightarrow \text{Latitude} = 0.8 \text{ Lon}$$

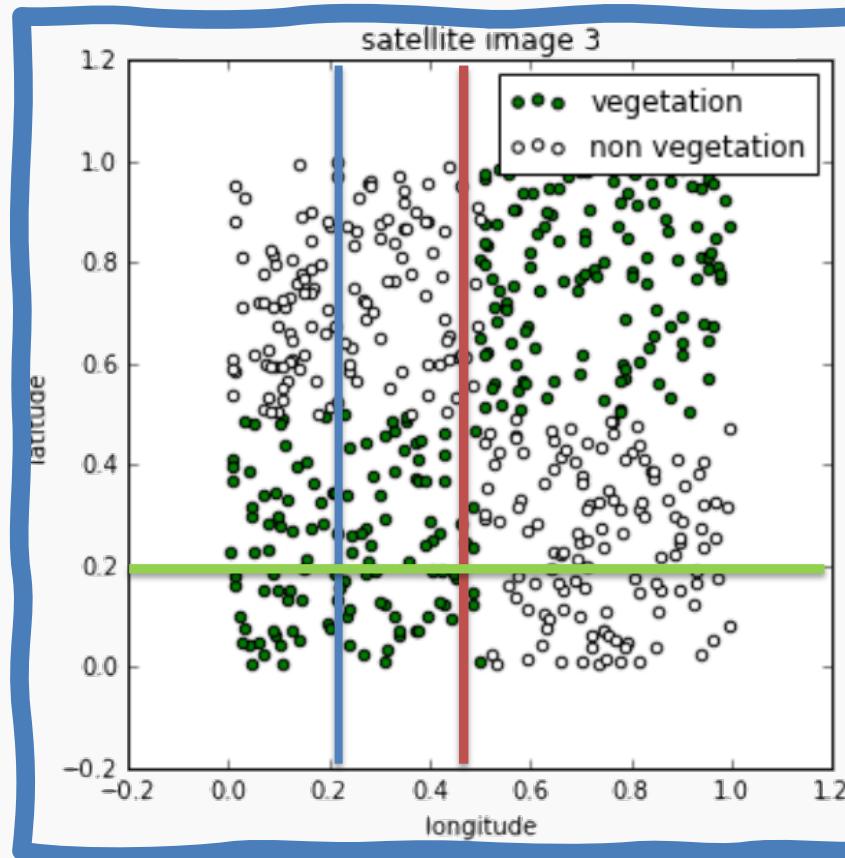

Geometry of Data

Complicate decision boundaries can not be explained with LogRegression.

Geometry of Data

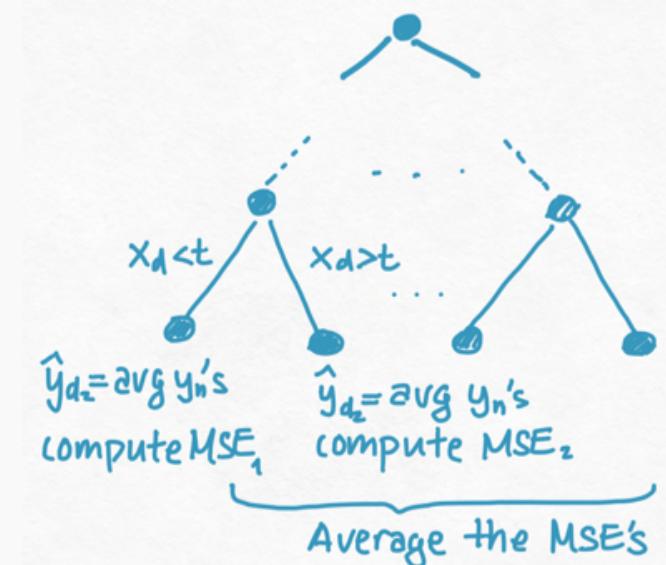

But can be using Trees. Which one represents the first split of a decision tree?

Decision Trees

To learn a decision tree model, we take a greedy approach:

1. Start with a node containing all the data.
2. If **stopping condition** is not met:
 - A. Choose the ‘optimal’ predictor and threshold and divide the data in the node into two sets.
3. For each new node, repeat step 2.

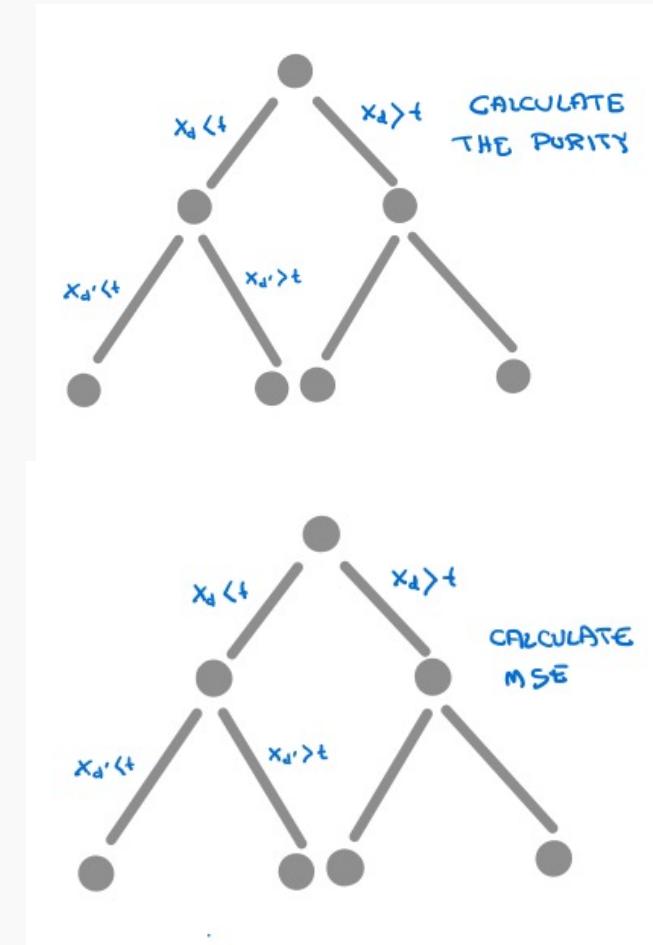

Decision Trees: Splitting Criteria

Splitting Criteria:

For classification, purity of the regions is a good indicator the performance of the model. Entropy as a splitting criterial minimizes the cross-entropy (greedy). Gini is also a splitting criteria.

For regression, we want to select a splitting criterion that promotes splits that improves the predictive accuracy of the model as measured by the MSE

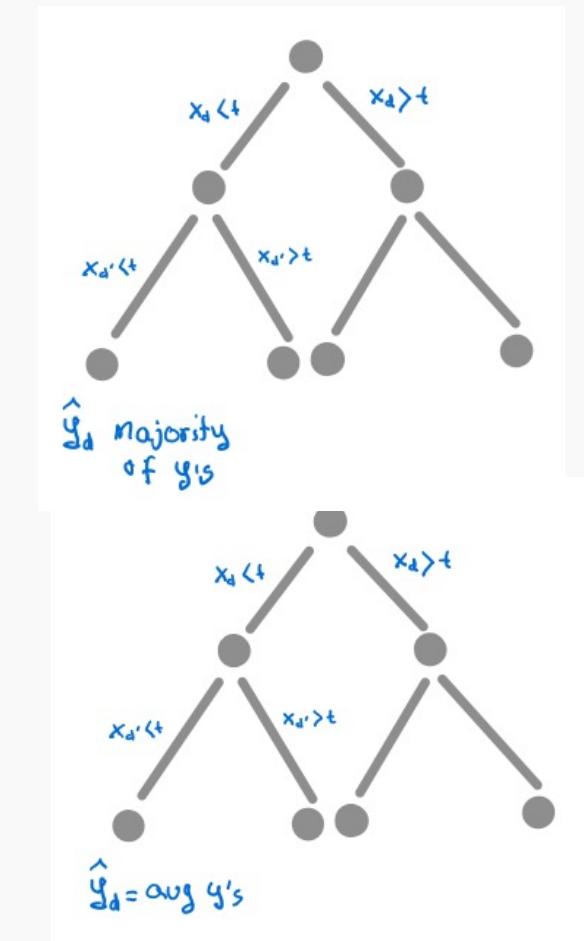

Decision Trees: Prediction

Prediction:

For classification, we label each region in the model with the label of the class to which the **plurality** of the points within the region belong.

For regression, we predict with the **average** of the output values of the training points contained in the region.

Stopping Conditions

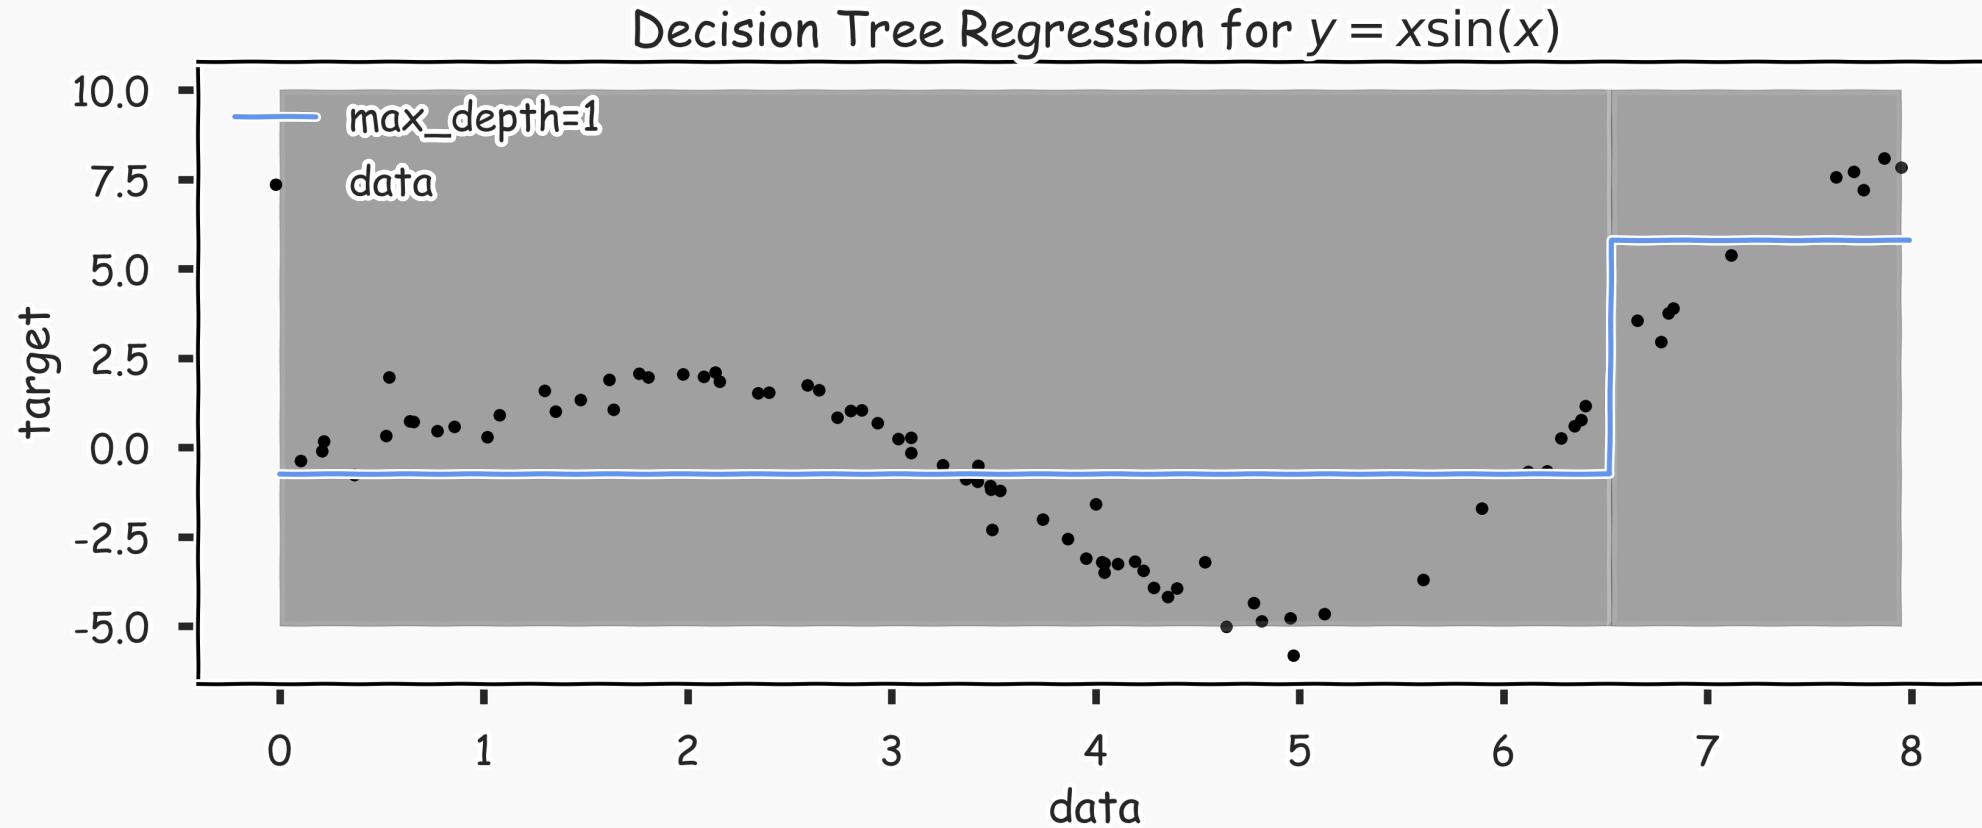

The stopping condition is usually a maximum depth or a minimum MSE.

But others common simple stopping conditions:

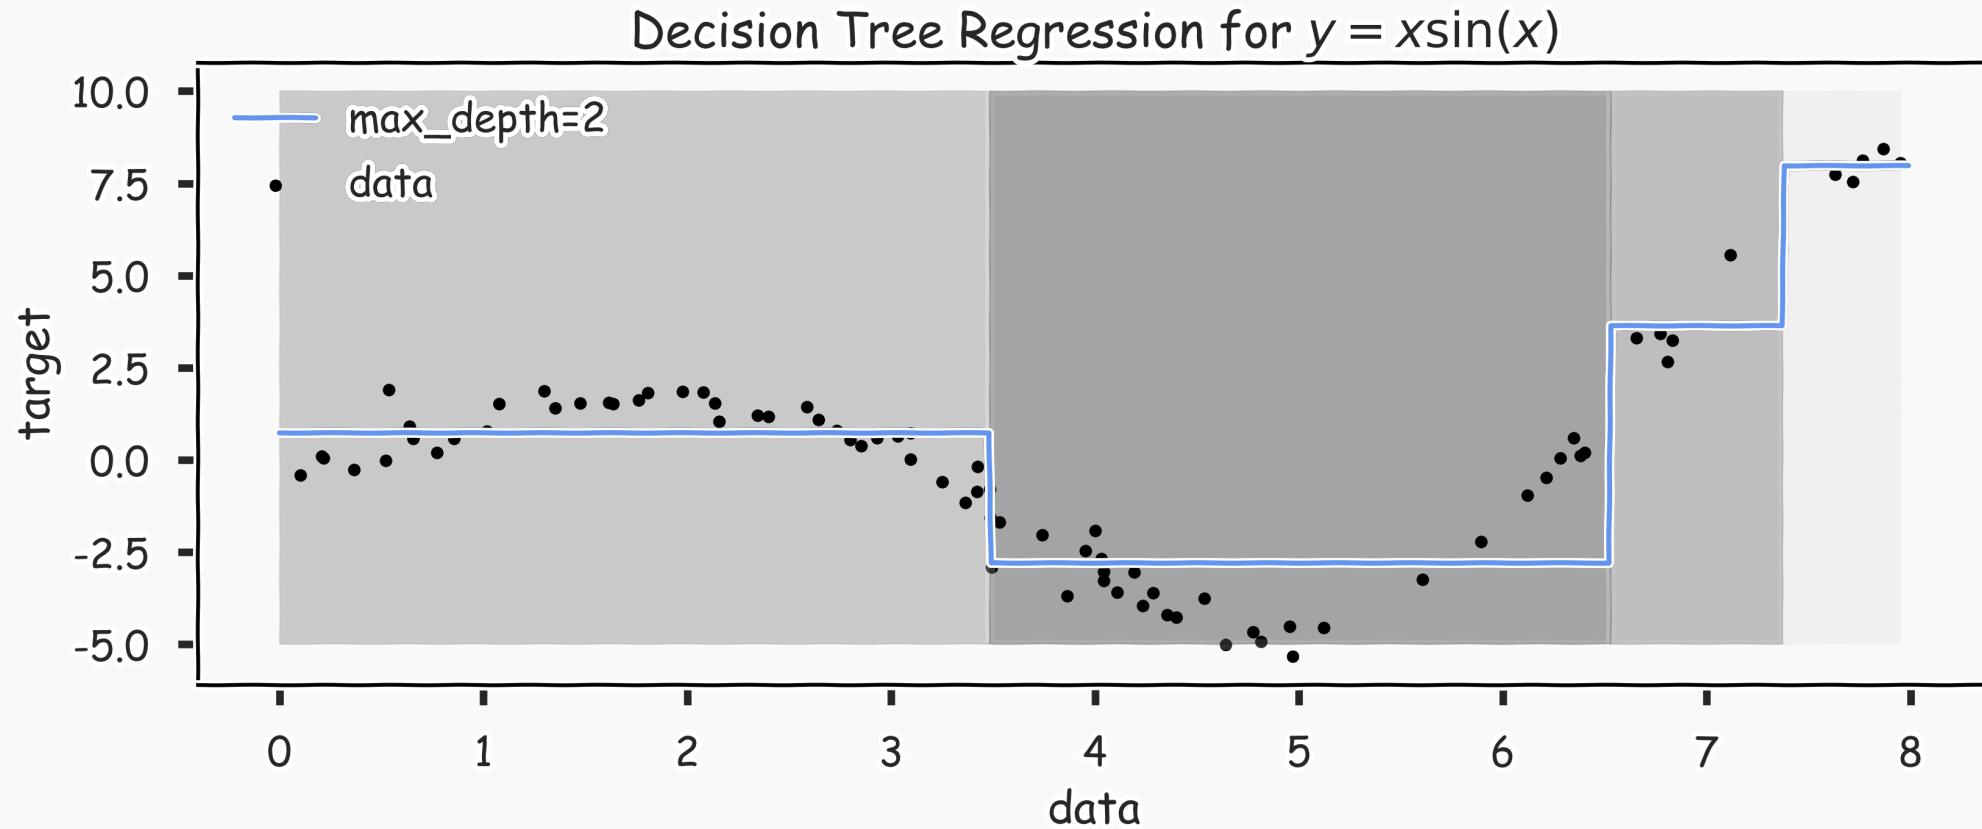

- Don't split a region if all instances in the region belong to the same class.
- Don't split a region if the number of instances in the sub-region will fall below pre-defined threshold (`min_samples_leaf`).
- Don't split a region if the total number of leaves in the tree will exceed pre-defined threshold.
- Don't split if the gain in purity, information, reduction in entropy or MSE of splitting a region R into R_1 and R_2 is less than some pre-defined threshold.

Overfitting

When tree is too shallow, it cannot divide the input data into enough regions, so the model underfits. When the tree is too deep it cuts the input space into too many regions and fit to the noise of the data -> overfits.

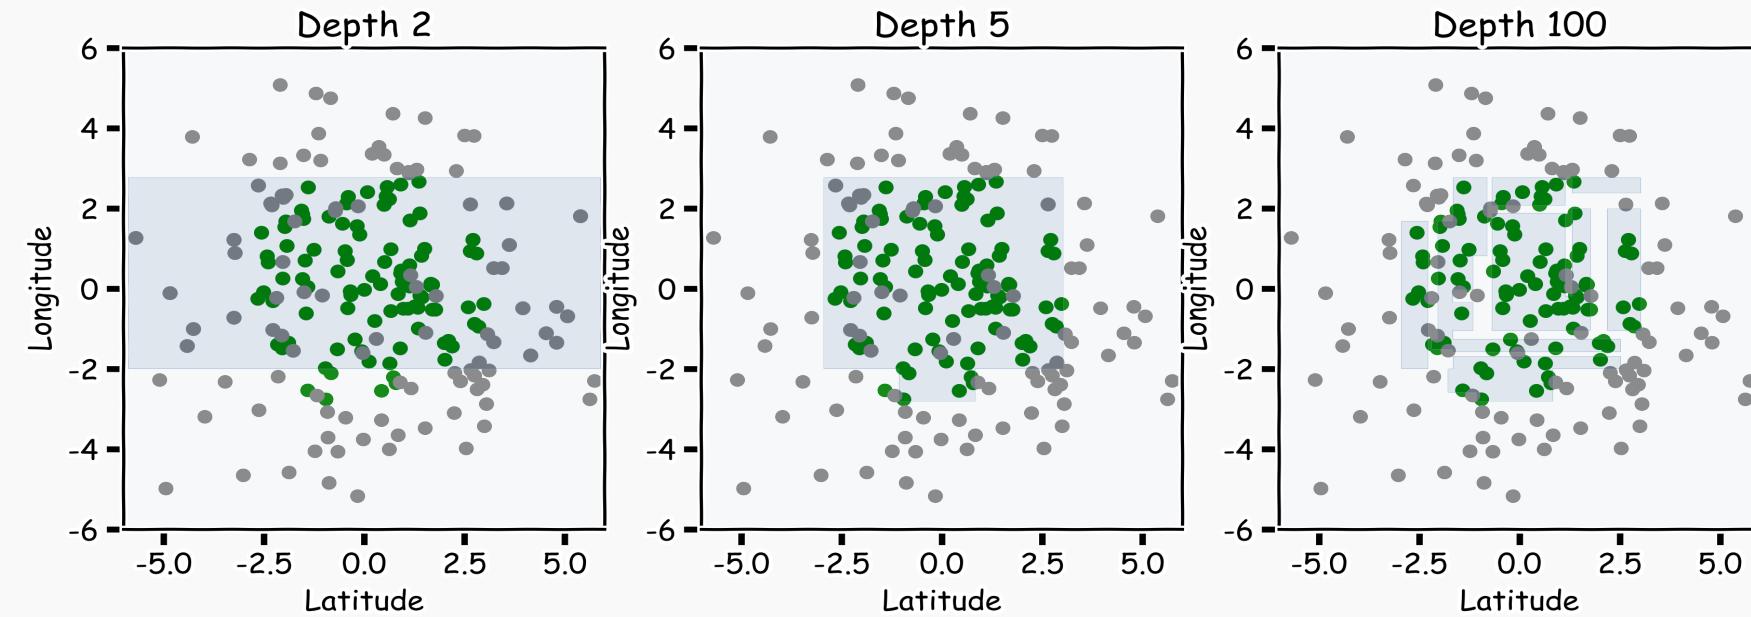

Overfitting

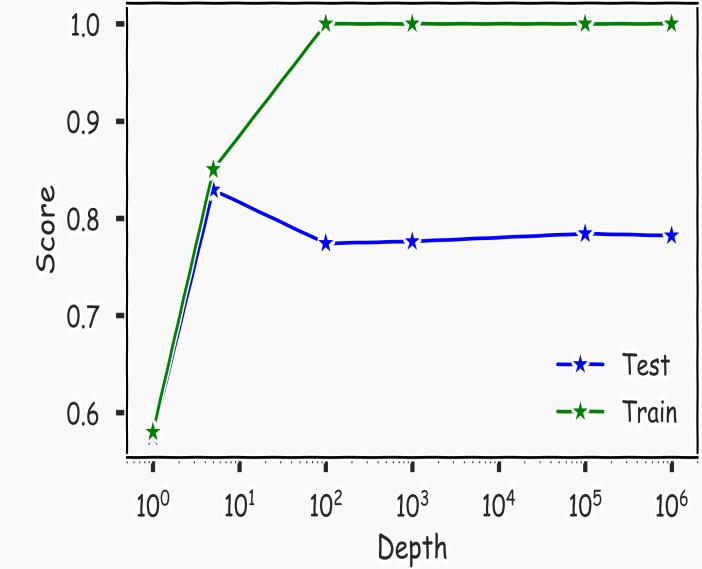

Avoid overfitting by pruning or limiting the depth of the tree and using CV.

Reduce the variance: Depth of the tree

We've seen that large trees have high variance and are prone to overfitting.

Use train/validation or cross validation to estimate the best depth.

Limitations of Decision Tree Models

Decision trees models are highly interpretable and fast to train, using our greedy learning algorithm.

Limitations of Decision Tree Models

Decision trees models are highly interpretable and fast to train, using our greedy learning algorithm.

However, to **capture a complex decision boundary** (or approximate a complex function), we need to use a large tree (since each time we can only do axis-aligned splits).

Limitations of Decision Tree Models

Decision trees models are highly interpretable and fast to train, using our greedy learning algorithm.

However, to **capture a complex decision boundary** (or approximate a complex function), we need to use a large tree (since each time we can only do axis-aligned splits).

We've seen that large trees have high variance and are prone to overfitting.

Limitations of Decision Tree Models

Decision trees models are highly interpretable and fast to train, using our greedy learning algorithm.

However, to **capture a complex decision boundary** (or approximate a complex function), we need to use a large tree (since each time we can only do axis-aligned splits).

We've seen that large trees have high variance and are prone to overfitting.

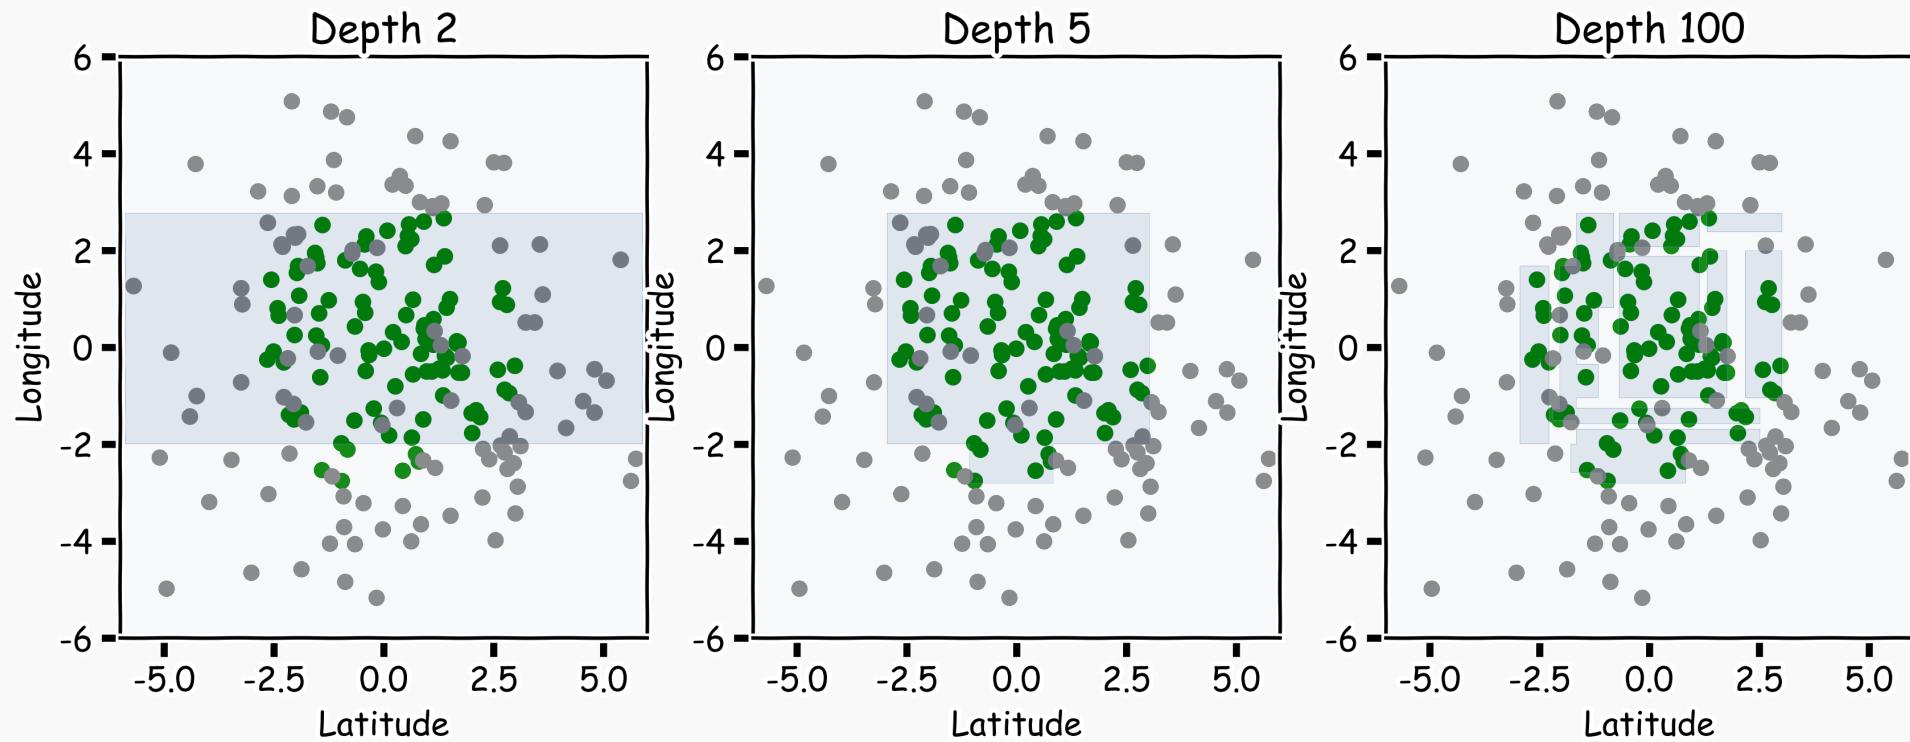

For these reasons, in practice, decision tree models often underperform when compared with other classification or regression methods.

Bagging

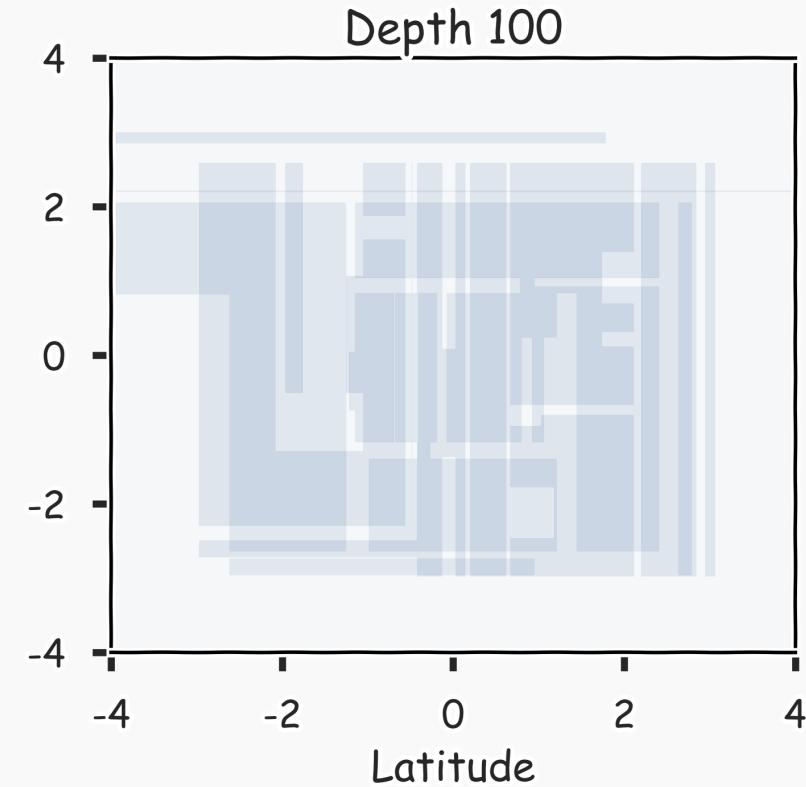

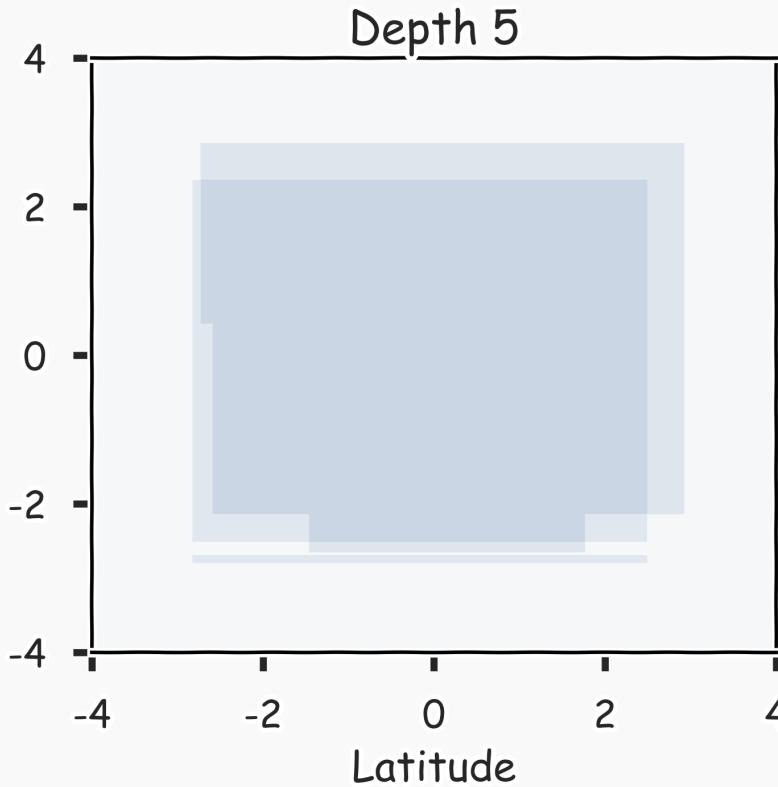

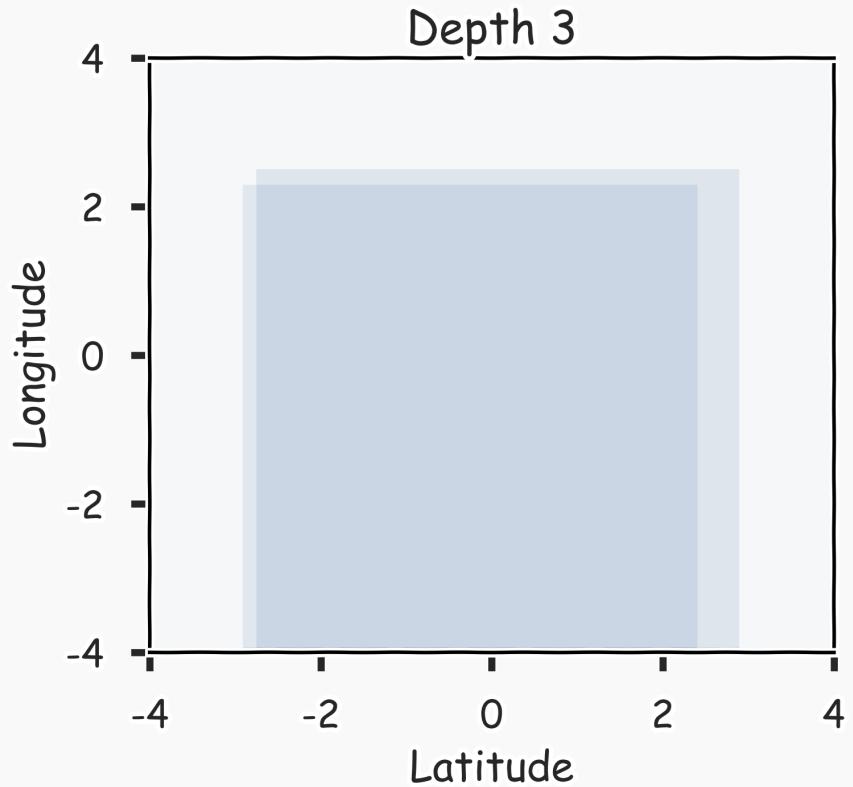

Bagging

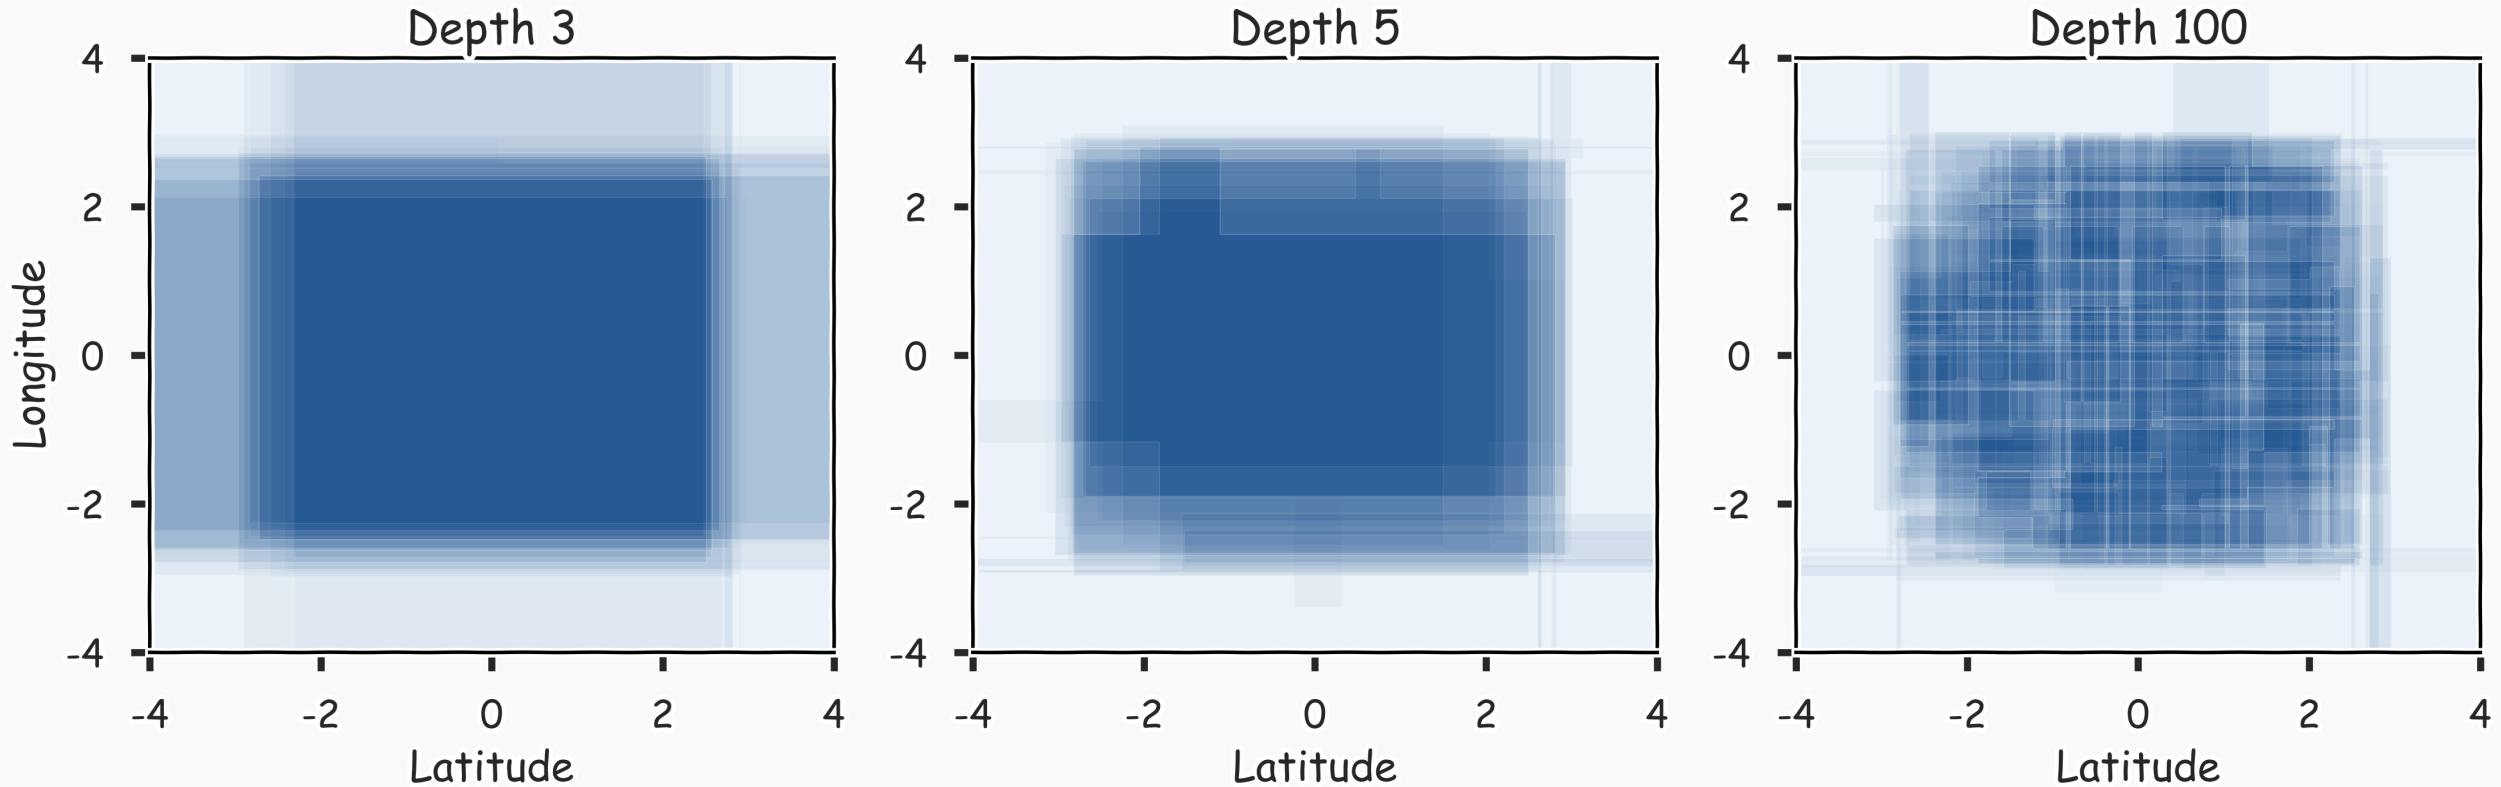

My favorite reality: magic realism \rightarrow bootstrap

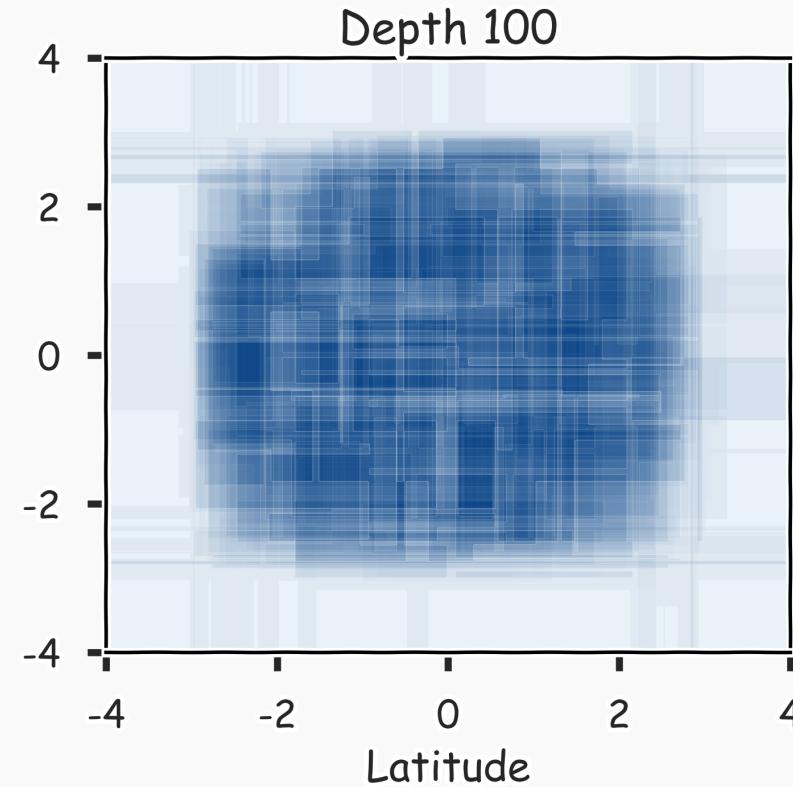

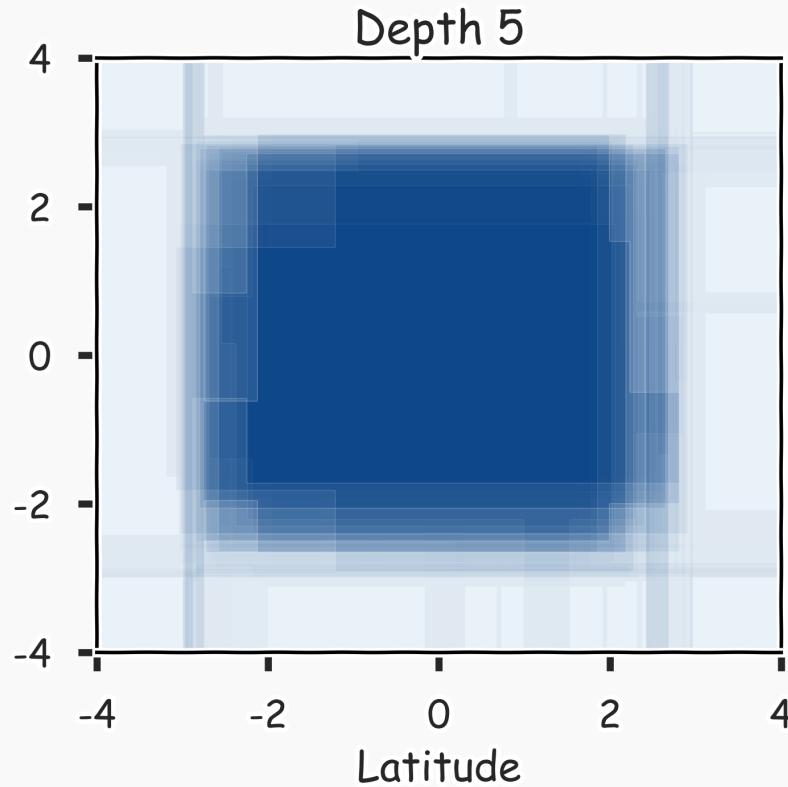

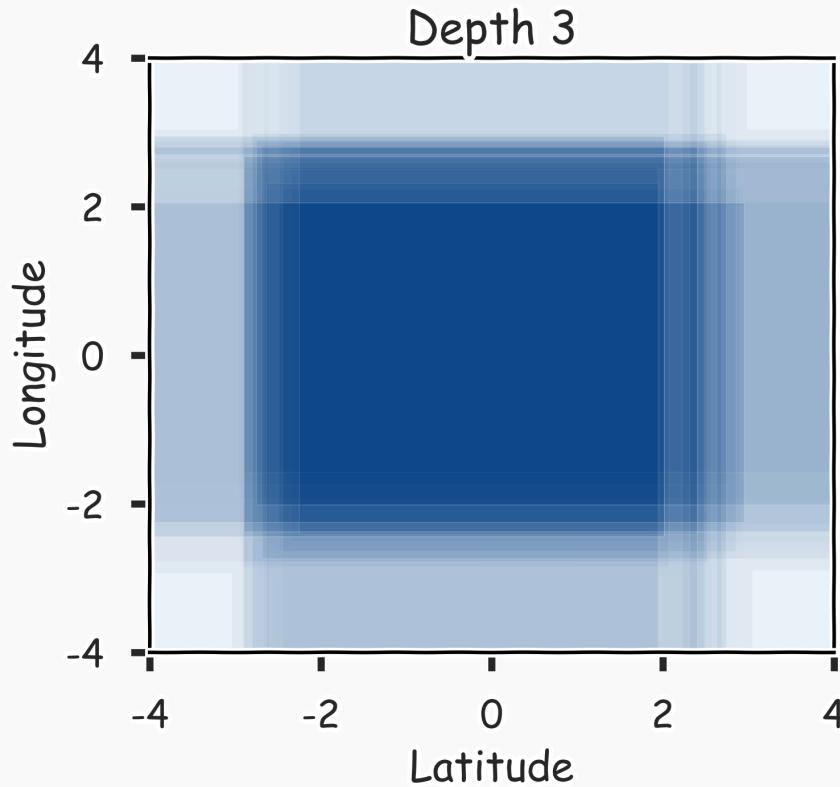

Combine them? 2 magic realisms

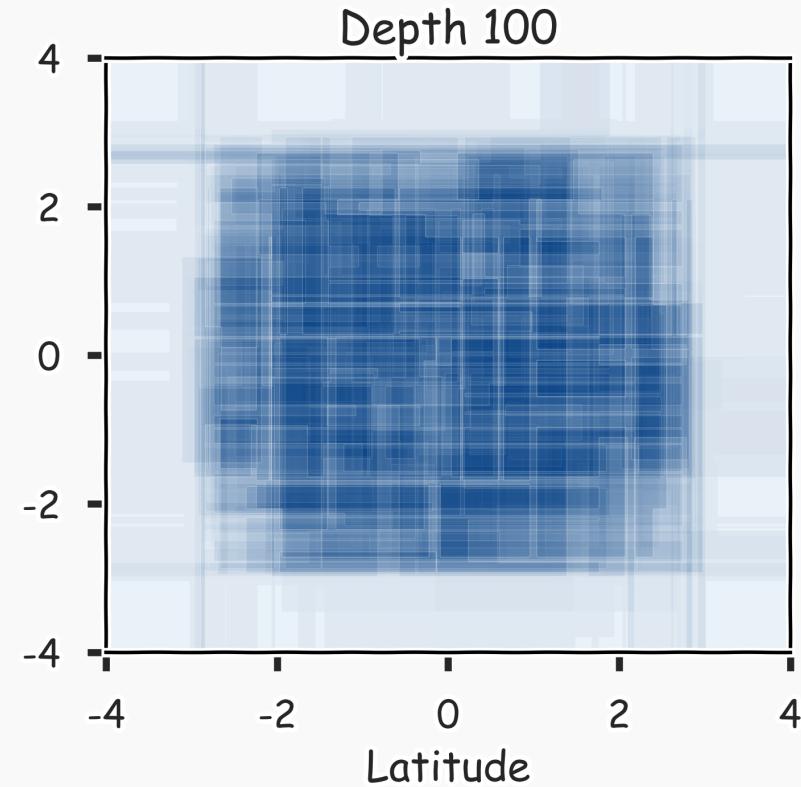

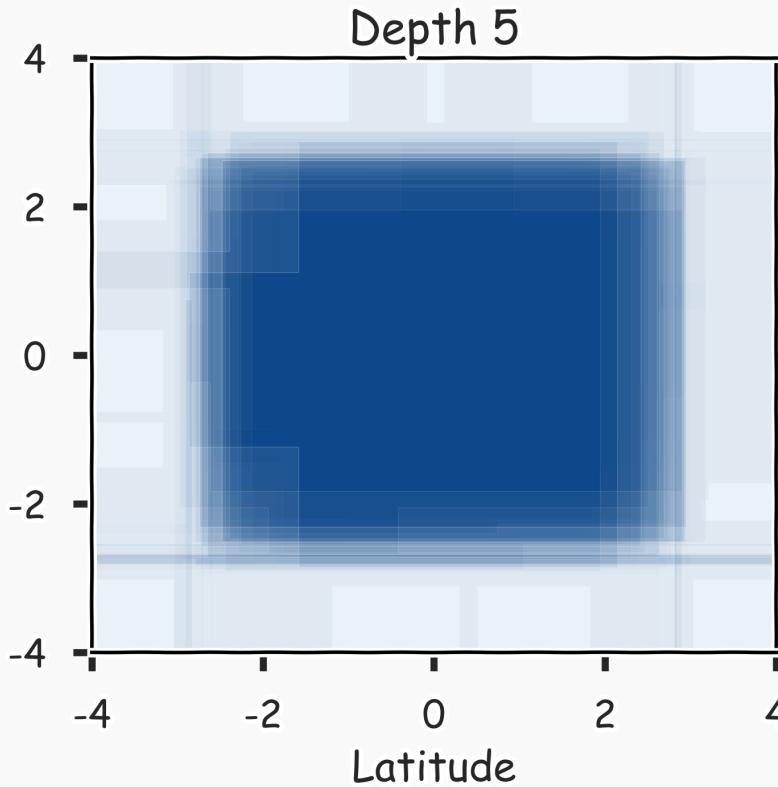

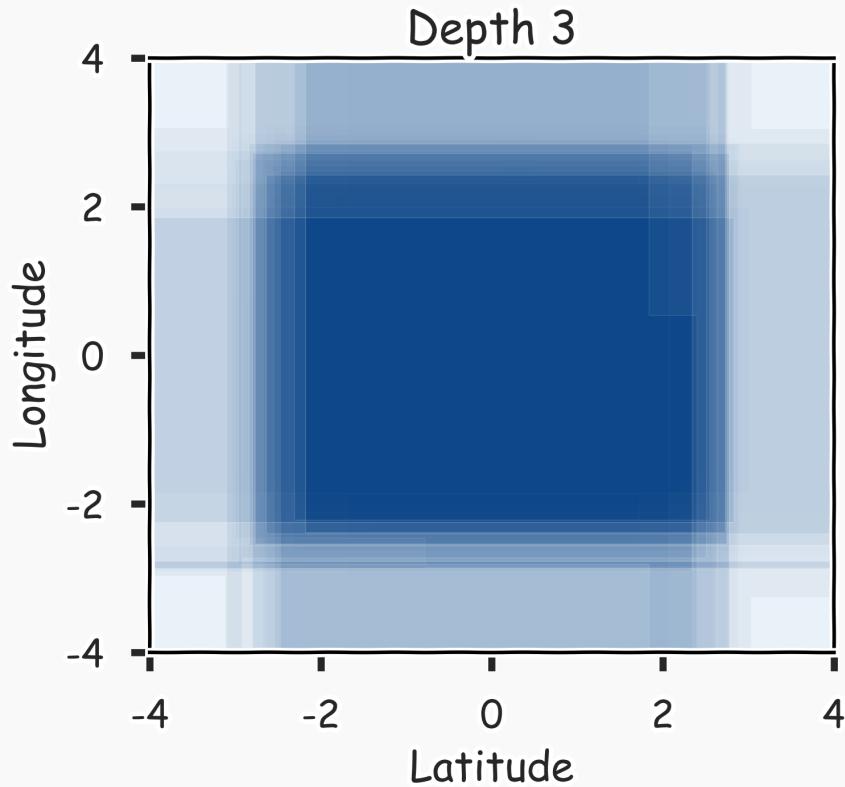

20 magic realisms

100 magic realisms

300 magic realisms

Bagging

One way to adjust for the high variance of the output of an experiment is to perform the experiment multiple times and then average the results.

The same idea can be applied to high variance models:

1. **Bootstrap**: we generate multiple samples of training data, via bootstrapping. We train a deeper decision tree on each sample of data.
2. **Aggregate**: for a given input, we output the averaged outputs of all the models for that input.

This method is called **Bagging** (Breiman, 1996), short for, of course, **Bootstrap Aggregating**.

For classification, we return the class that is outputted by the plurality of the models. For regression we return the **average** of the outputs for each tree.

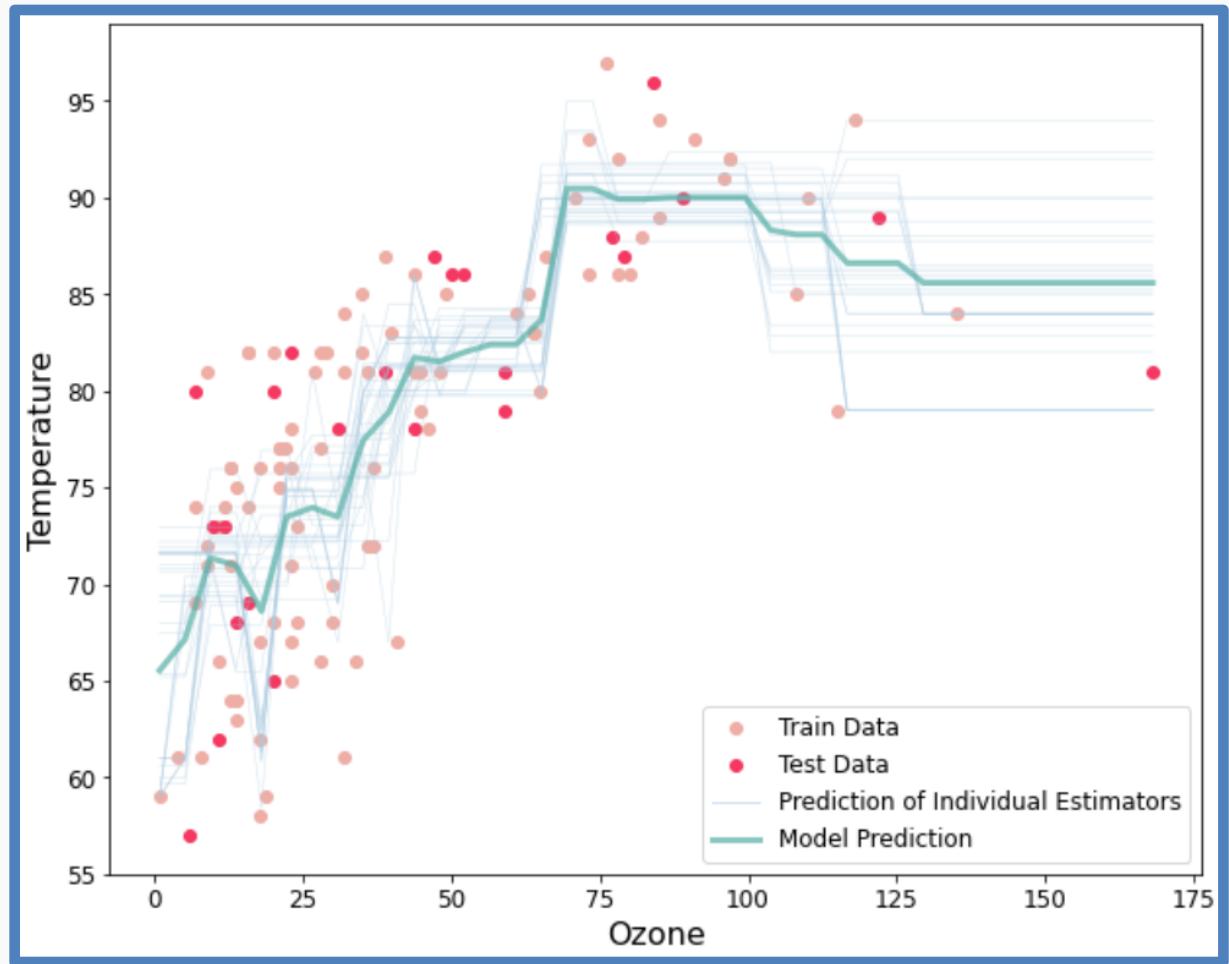

Bagging

Bagging enjoys the benefits of:

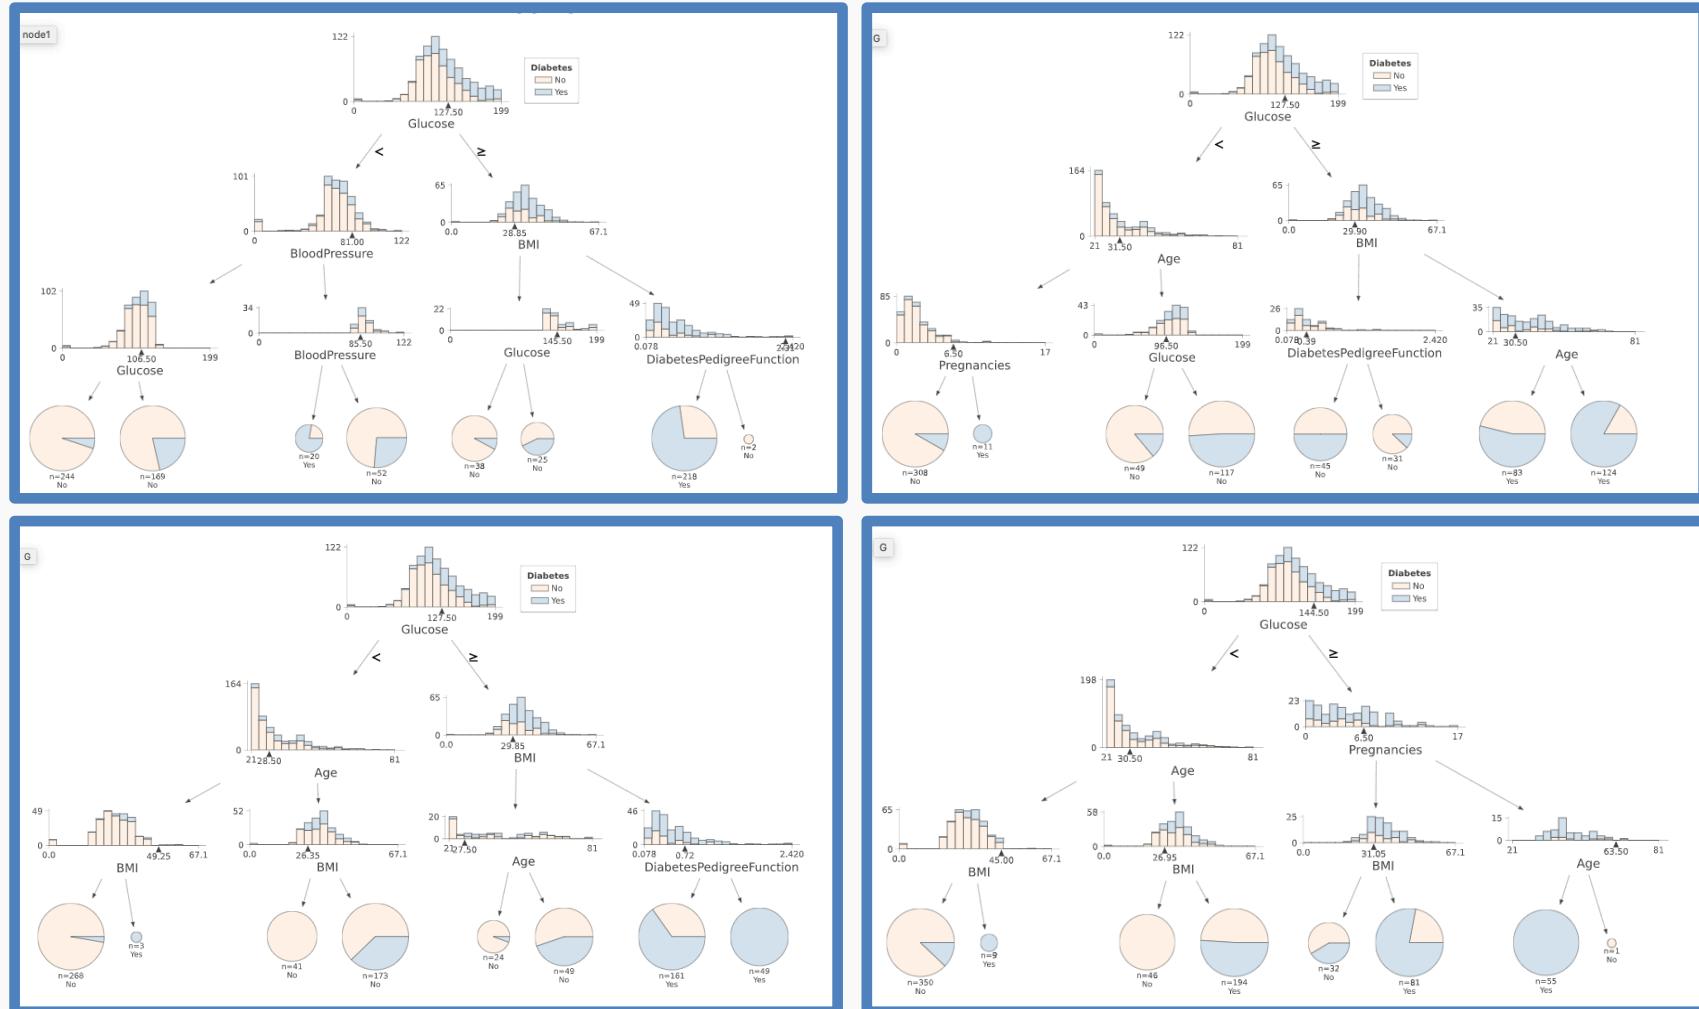

1. **High expressiveness** - by using deeper trees each model is able to approximate complex functions and decision boundaries.
2. **Low variance** - averaging the prediction of all the models reduces the variance in the final prediction, assuming that we choose a sufficiently large number of trees.

Bagging (regression)

The resulting tree is the average of all tree (estimators).

Bagging (classification)

For each bootstrap, we build a decision tree. The results is a combination (majority) of the predictions from all trees.

Bagging

Question: Do you see any problems?

Bagging

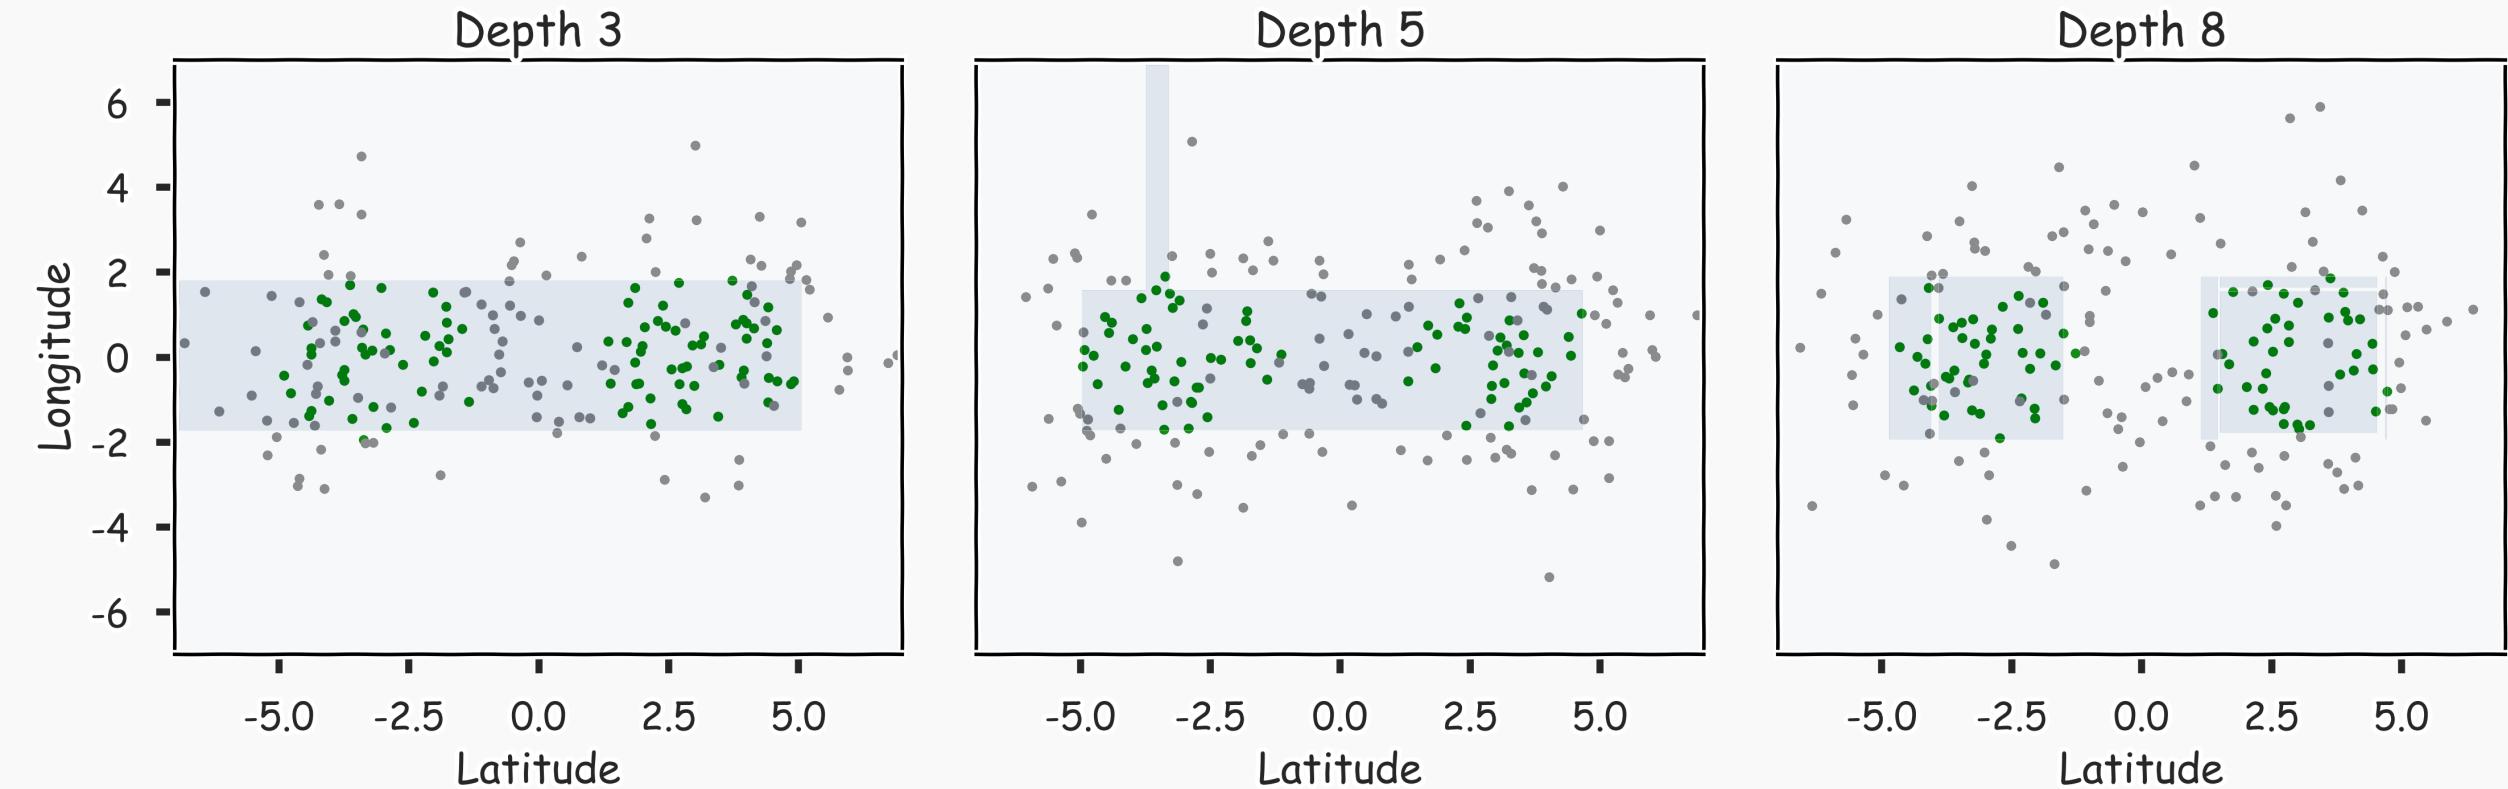

Question: Do you see any problems?

- If trees are too shallow it can still **underfit**.
- Still some **overfitting** if the trees are too large.
- **Interpretability**:

The **major drawback** of bagging (and other **ensemble methods** that we will study) is that the averaged model is no longer easily interpretable - i.e. one can no longer trace the ‘logic’ of an output through a series of decisions based on predictor values!

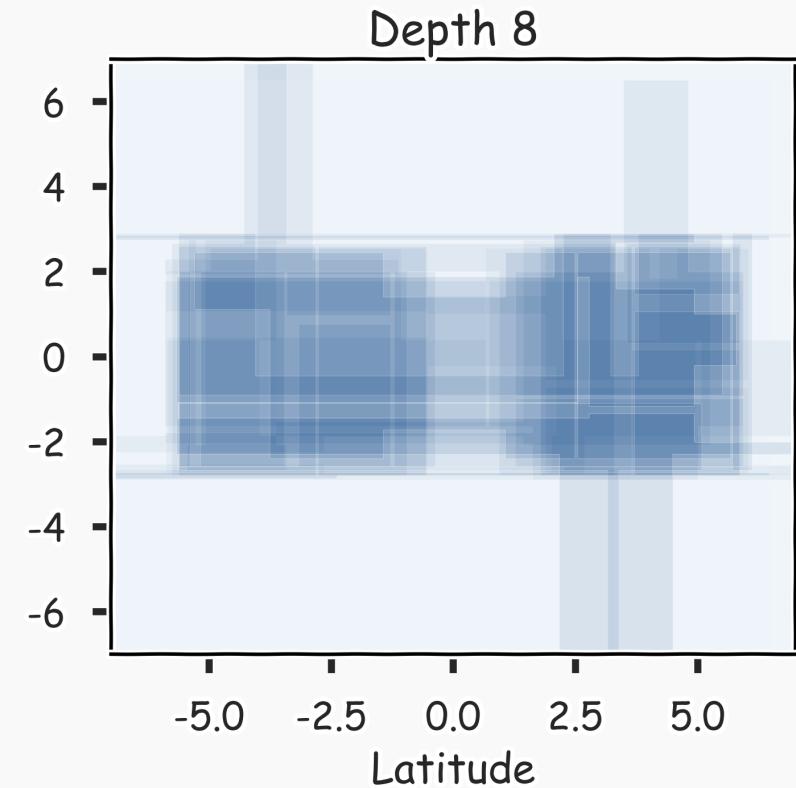

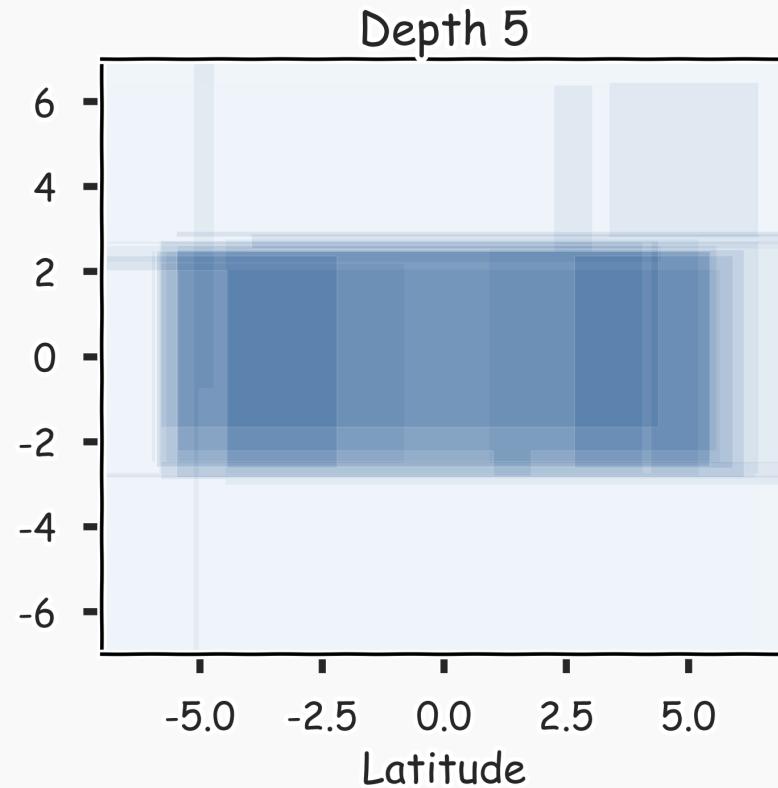

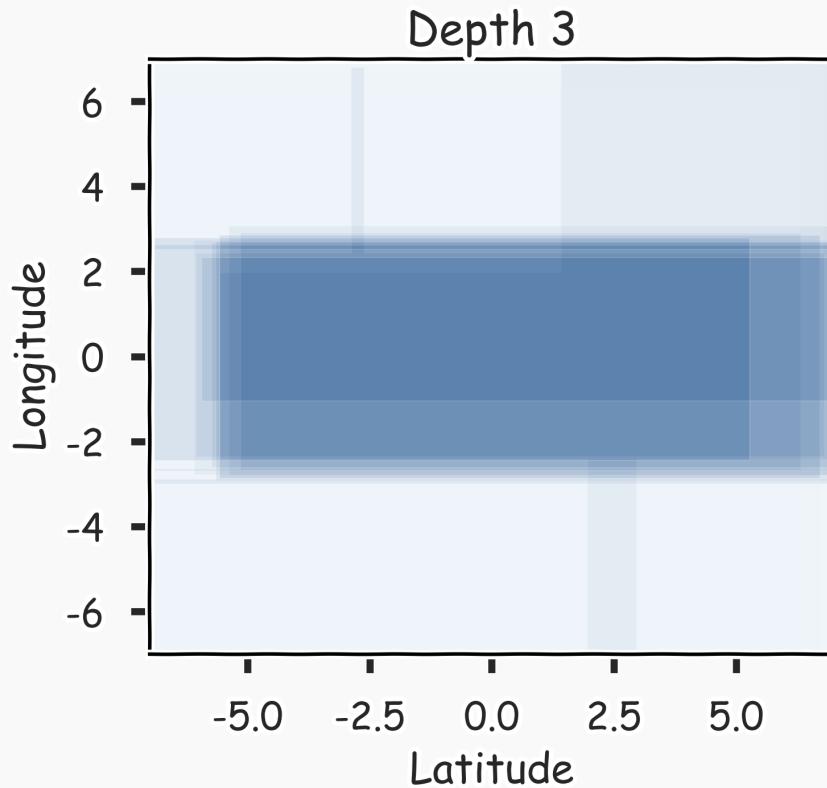

Case of underfitting

Consider the dataset below. To capture the pattern we need deeper tree.

Case of underfitting

Here we fit 100 trees using bootstrapped samples. Even with multiple estimators, the shallow tree will not be able to capture the real pattern.

Bagging

Question: Do you see any problems?

- If trees are too shallow it can still underfit.
- Still some overfitting if the trees are too large.

Cross Validation

Classification

$$\hat{y}_{i,pw} = \text{majority}(\hat{y}_i)$$

$$e_i = \mathbb{I}(\hat{y}_{i,pw} \neq y_i)$$

Regression

$$\hat{y}_{i,pw} = \sum_{j \in B} \hat{y}_{i,j}$$

$$e_i = (y_i - \hat{y}_{i,pw})^2$$

OOB Error

We average the point-wise out-of-bag error over the full training set.

Classification

$$Error_{OOB} = \frac{1}{B} \sum_i^B e_i = \frac{1}{B} \sum_i^B \mathbb{I}(\hat{y}_{i,pw} \neq y_i)$$

Regression

$$Error_{OOB} = \frac{1}{B} \sum_i^B e_i = \frac{1}{B} \sum_i^B (y_i - \hat{y}_{i,pw})^2$$

Out-of-Bag Error

Bagging is an example of an **ensemble method**, a method of building a single model by training and aggregating multiple models.

With ensemble methods, we get a new metric for assessing the predictive performance of the model, the **out-of-bag error**.

Given a training set and an ensemble of models, each trained on a bootstrap sample, we compute the **out-of-bag error** of the averaged model by

1. For each point in the training set, we average the predicted output for this point over the models whose bootstrap training set excludes this point. We compute the error or squared error of this averaged prediction. Call this the point-wise out-of-bag error.
2. We average the point-wise out-of-bag error over the full training set.

Bagging

Question: Do you see any problems?

- If trees are too shallow it can still underfit.
- Still some overfitting if the trees are too large.
- **Interpretability:**

The **major drawback** of bagging (and other **ensemble methods** that we will study) is that the averaged model is no longer easily interpretable - i.e. one can no longer trace the ‘logic’ of an output through a series of decisions based on predictor values!

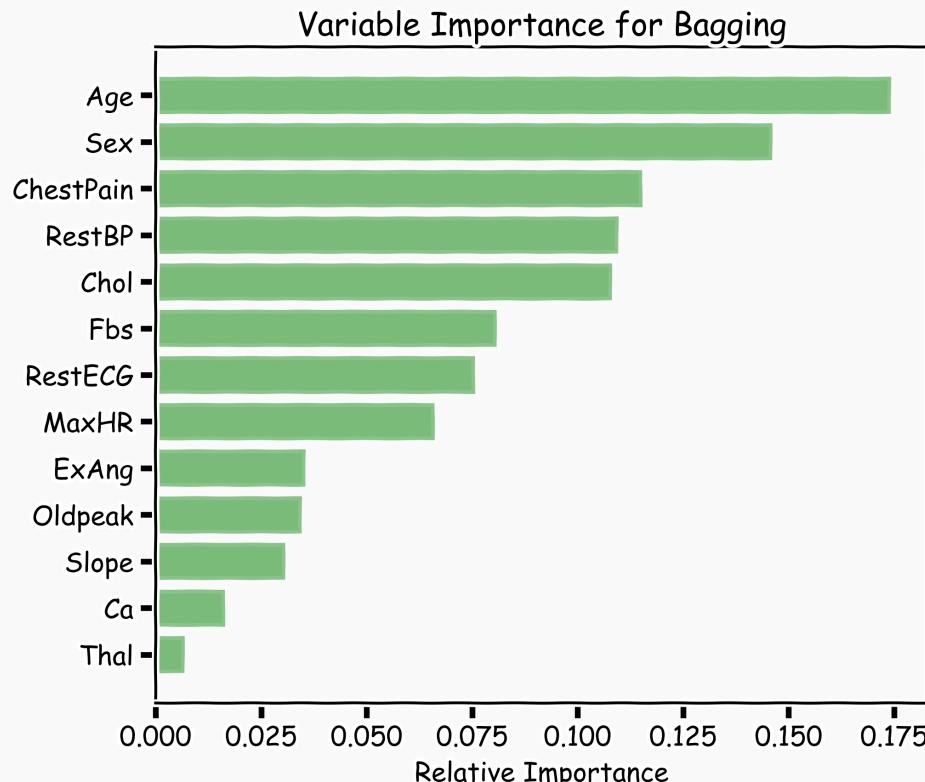

Outline

- Review of Decision Trees
- Bagging
- Out of Bag Error (OOB)
- **Variable Importance**

Variable Importance for Bagging

Calculate the total amount that the MSE (for regression) or Gini index (for classification) is decreased due to splits over a given predictor, averaged over all B trees.

100 trees, max_depth=10

Improving on Bagging

In practice, the ensembles of trees in Bagging tend to be **highly correlated**.

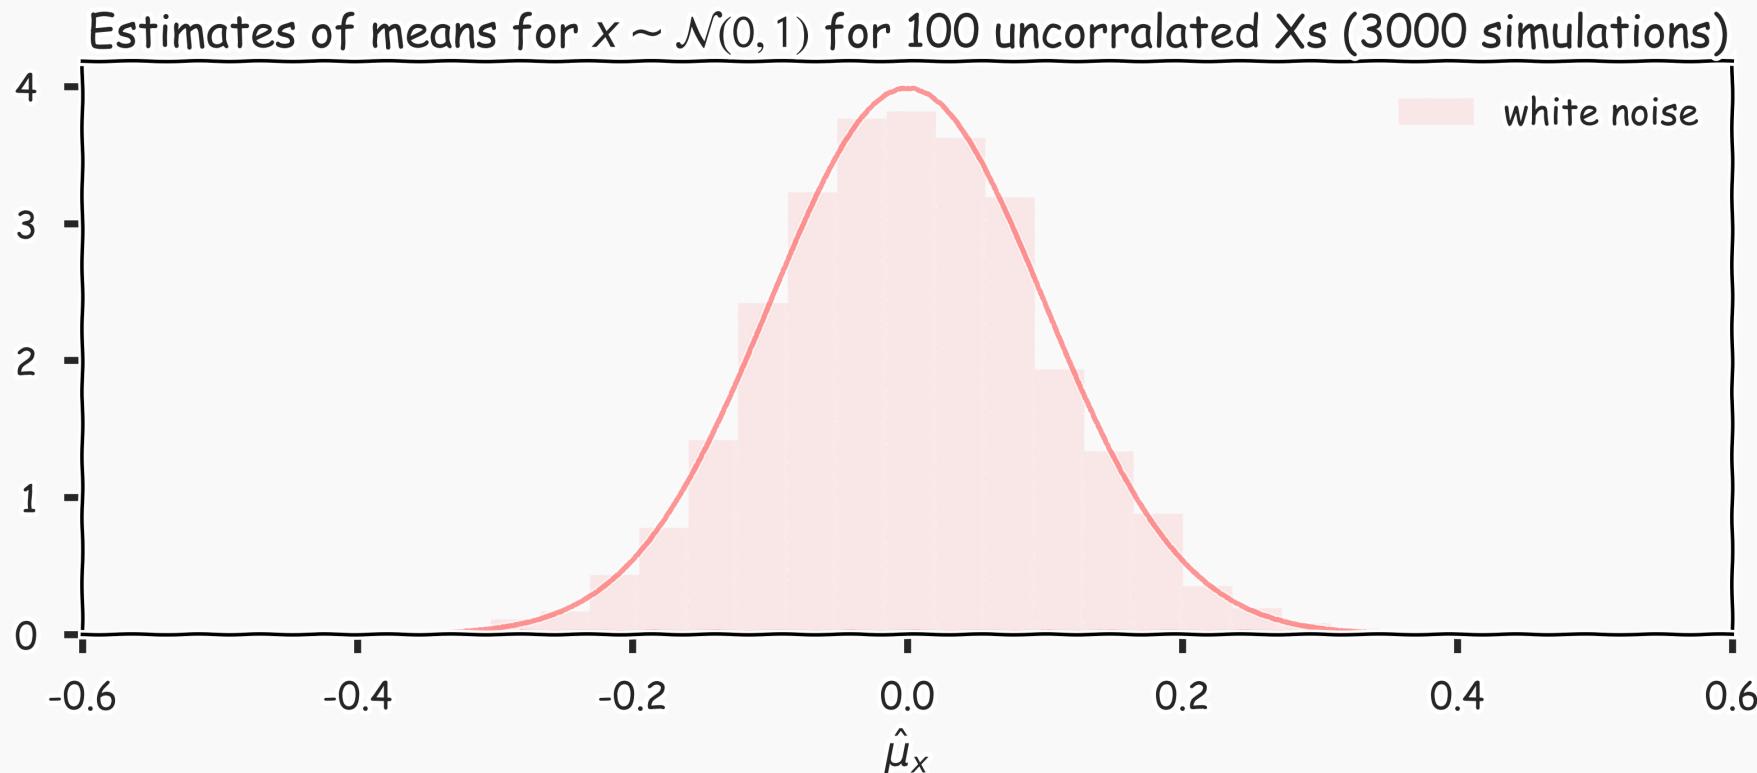

Suppose we have an extremely strong predictor, x_j , in the training set amongst moderate predictors. Then the greedy learning algorithm ensures that most of the models in the ensemble will choose to split on x_j in early iterations.

However, we assumed that each tree in the ensemble is **independently** and **identically** distributed, with the expected output of the averaged model the same as the expected output of any one of the trees.

Improving on Bagging

Recall, for B number of identically and independently distributed variable, X , with variance σ^2 , the variance of the estimate of the mean is :

$$\text{var}(\hat{\mu}_x) = \frac{\sigma^2}{B}$$

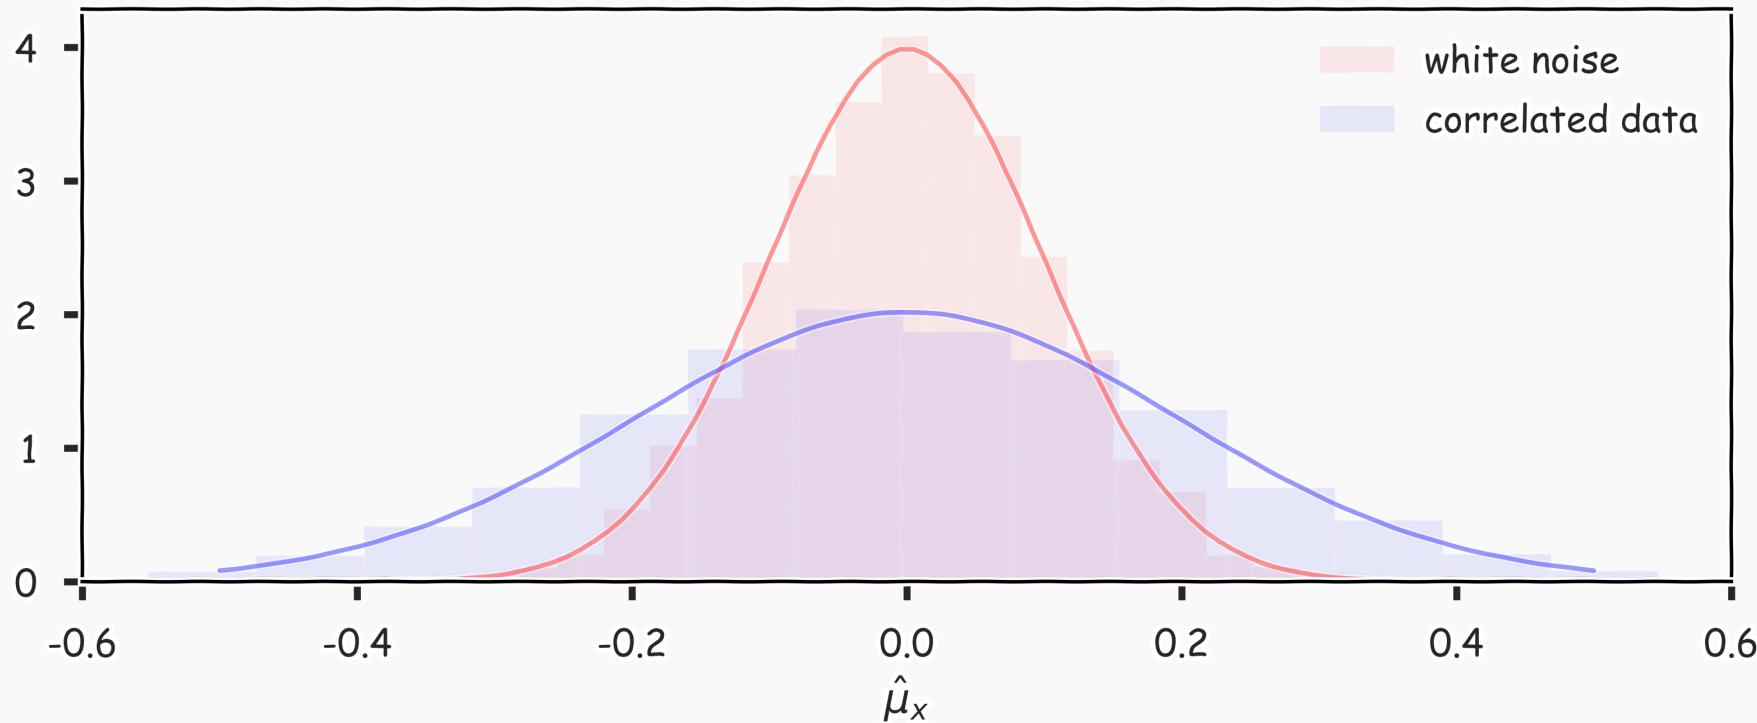

Improving on Bagging

For B number of identically but not independently distributed variables with pairwise correlation ρ and variance σ^2 , the variance of their mean is

$$\text{var}(\hat{\mu}_x) \propto \sigma^2(1 + \rho^2)/B$$

Estimates of means for correlated xs, $\rho = 0.5$, for 100 Xs. Here we show the results for 3000 simulations

Another cliff hanger in CS109A

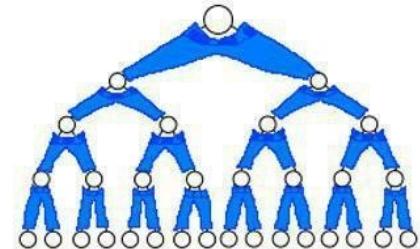

What to do? 🤔

- 👉 Today's lucky student: The most charming student in the breakout room
- 👉 Instructions (a reminder):
 - 👉 Listen to your peers' opinions and suggestions. Ask questions of each other ("What do you think"). Do not just lead others in the room without **including** everyone.
 - 👉 Make sure you do not **cut-off or ignore** what other students are trying to contribute.
- 👉 If you have questions, please reach out to the teaching staff. You can buzz us to come help, or if all else fails, come to the main room.
